Keywords: microstructure, mechanical properties, creep, corrosion resistance, magnesium alloy

1. Introduction

The growing demand for more fuel-efficient vehicles to reduce energy consumption and air pollution is a challenge for the automotive industry. The characteristic properties of magnesium alloys, low density, high strength stiffness to weight ratio, good damping capacity and diecastability, and recycling potential make it the ideal candidate for heavier materials (steel, aluminum) to reduce the weight of the car. The widely used magnesium alloys are Mg–Al series, such as AZ91 and AM60, which have excellent castability, good mechanical properties at room temperature and low cost. However, the use of these magnesium alloys have been limited because of their poor heat resistance.1 The previous investigation2 showed that the grain boundary sliding is an important part of the deformation mechanism at elevated temperatures in Mg–Al based alloys. Therefore, to improve heat resistance in Mg–Al based alloy, it seems an effective method to develop an alloy containing thermal stable intergranular phases, which can suppress the grain boundary sliding.

Recent studies indicate that addition of silicon to Mg–Al–Zn alloy can achieve substantial increases in strength, toughness, etc. because Mg3Si formed by the addition of Si is the substantially effective strengthening particles, which exhibit a high melting temperature (1085 °C), low density (1.9 g/cm3), high elastic modulus (120 GPa), and a low thermal expansion coefficient (7.5 × 10^-6 °C^-1).3 However, the magnesium alloys containing Si are only limited to the diecast, which has a rapid solid rate. Mg3Si compounds are prone to forming undesirable coarse Chinese script under conventional (or slower) solidification process. To use of magnesium alloys containing Mg3Si particles for sand casting or permanent mould casting, microstructural refinement should be achieved.

It has been reported that the as-cast microstructure of Mg alloys containing Mg3Si particles could be refined by P or Ca addition.4 However, addition of phosphor can produce ignition and result in large quantity of sick smoke. In recent studies,5 we found a more effective modifier of Sb than Ca in Mg–Al–Zn–Si alloys. This paper reports the results of our preliminary experiments on the effects of Sb and MM simultaneous additions on the microstructural development, tensile strength, creep properties and corrosion resistance of Mg–5Al–1Zn–1Si alloy obtained by a permanent mould gravity casting process.

2. Experimental Procedure

Three alloys of which the compositions are listed in Table 1 were prepared in mild steel crucible under the protection of mixed gas of CO2/0.5%SF6 using commercial stock. Tensile specimens with a gauge section of 15 mm × 3.5 mm × 2 mm were cut by electric spark machining from the bottom of ingots. Before testing all the specimens were solution heat-treated at 410 °C for 10 hours, water quenched, and then aged at 200 °C for 2 hours. All specimens for microstructural characterization were cut from the same positions on the ingots at 10 mm from the castings. Phases in the Mg–5Al–1Zn–1Si–X alloys were analyzed by D/MaxIII A-12KW-Cu type XRD analyzer operated at 40 kV and 120 mA. Chemical analysis of the cast experimental alloys was performed by inductively coupled plasma (ICP). The electropolished samples were examined in a Philip-505 scanning electron microscope equipped with an energy dispersive X-ray spectrometer (EDS) to investigate the microstructures and second phases in the alloys. The grain size was determined using a large number of non-overlapping measurements.

The microstructure of the permanent mould cast Mg–5Al–1Zn–1Si based alloys is illustrated in Fig. 3. A typical micrograph of Mg–5Al–1Zn–1Si alloy is shown in Fig. 3(b). The microstructure consists of Chinese-script type Mg$_2$Si particles with interdendritic Mg$_{17}$Al$_{12}$ phases in matrix (α-Mg). When the as-cast specimens of the alloys were solution treated at 420°C for 10 hours (T4 condition), almost all of β-phase dissolved in the matrix and only Chinese-script type Mg$_2$Si particle existed, as shown in Fig. 1(b), which indicated that Mg$_2$Si has excellent thermal stability at elevated temperatures. With the addition of Sb, two microstructural changes can be observed clearly: (1) morphology of the Mg$_2$Si particles changed from coarse Chinese script shape to the fine polygonal shape, (2) the average size of grain decreased from 134 to 68 μm (Figs. 1(b) and (c)). With the mischmetal microaddition to Mg–5Al–1Zn–1Si–0.5Sb alloy, the microstructure was not influenced obviously. The refinement of grain may be due to the formation of lots of finely distributed polygonal type Mg$_2$Si particles in the interface of liquid-solid former during solidification.

Figure 2 is the XRD results of Mg–5Al–1Zn–1Si–0.5Sb alloy. It is recognized peaks from Mg$_2$Si former during solidification. (a). The XRD results of Mg–5Al–1Zn–1Si–0.5Sb alloy shows a typical result on crystallization center in the Sb-containing alloys.

### 3.2 Mg$_2$Si phase heterogeneous nucleation

Figure 3(a) shows micrograph of Mg$_2$Si particles in the alloy containing 0.5Sb. It is interesting that Mg$_2$Si particles contain small particles inside (labeled “A”), which presumably act as nucleation sites for Mg$_2$Si particles. Figure 3(a) shows a typical result on crystallization center in the Sb-containing alloy obtained by magnified secondary electron image (SEI) of nucleus. Figure 3(b) shows the EDS spectra for the nucleus. It shows that the nucleus is enriched with Mg, Sb and Si. Combining the information from XRD and EDS spectrum shows that the nature of nucleus is possible to be Mg$_5$Sb$_2$.

In classical nucleation theory, nucleating can be facilitated when the foreign particle displays a small lattice mismatch (<6%S) with the nucleating solid phase. The results of calculation for some possible crystallographic orientations for Mg$_2$Si nucleation on the Mg$_5$Sb$_2$ particles show that when the orientation relationship between Mg$_2$Si phase and Mg$_5$Sb$_2$ phase is $(0001)_{Mg_2Si} \parallel (111)_{Mg_5Sb_2}$, the planar disregistry is the lowest (5.1%). Therefore, Mg$_5$Sb$_2$ can act as the heterogeneous nucleation for the Mg$_2$Si phase by this orientation relationship.

### 3.3 Solidification process of Mg–Al–Zn–Si–base alloys

Figure 4 shows a typical cooling curve for the Mg–5Al–1Zn–X based alloys under a cooling rate of 0.5°C/s. From the curves of solidification, the following information could be obtained: the practical temperature of the liquid metal at the moment of entry to the mold was 648°C and 621°C respectively, which was measured with a high sensitivity thermocouple. The wall of mold cavity chilled the liquid metal, causing the temperature of the liquid metal to rapidly drop. A little platform appeared in the curve at about 616°C for AZ51 and 606°C for SJTU-HM1 (The liquidus temperature of SJTU-HM1 is lower by 10°C than that of AZ51, which may be beneficial to the castability). With the decrease of temperature, the liquid metal starts to solidify. Owing to the high melting point of Mg$_2$Si particles, the Mg$_2$Si primarily precipitated. Followed by the onset of Mg($\alpha$) formation, and then the further growth of Mg$_2$Si phase and Mg($\alpha$) phase and ends at 407°C (another platform, as arrowhead shown in Fig. 4), which is actually the non-equilibrium eutectic temperature for L→Mg($\alpha$)+Mg$_{17}$Al$_{12}$, forming the divorced eutectic structure of [Mg($\alpha$)+Mg$_{17}$Al$_{12}$] as shown in Fig. 1(a).

### 3.4 Mechanical properties

The mechanical properties of the alloys with and without Sb and mischmetal addition of RE are compared in Table 2. It can be seen that Sb and RE microaddition to the alloy (SJTU-HM1) resulted in beneficial influence on improving the mechanical properties. It shows that the Sb- and RE-containing alloys have improved yield strength, ultimate tensile strength, elongation and apparent fracture toughness over the base alloy. It is obvious that the improvement of tensile strength was ascribed to three aspects: (1) small grain strengthening, (2) the change of morphology of Mg$_2$Si from Chinese-script type to polygonal type, since long cracks can easily nucleate along the interface between Chinese-script Mg$_2$Si particles and Mg matrix, and (3) the dispersion strengthening of fine particles (Mg$_2$Si and Mg$_5$Sb$_2$).

In addition, owing to its high melting point (1228°C) of those Mg$_5$Sb$_2$ particles which can not act as nucleus of Mg$_2$Si in Mg–5Al–1Zn–1Si are also effective strengthening phases for Mg alloy application at elevated temperatures, which may be contributed to the improvement of tensile strength at elevated temperatures.

### 3.5 Creep behavior

Figure 5 is several typical creep strain vs. time curves obtained from the constant-load and constant-temperature test (200°C/50 MPa) for the four kinds of alloys. The

simultaneous additions of Sb and mischmetal (MM) to Mg–5Al–1Zn–1Si alloy reduced the steady state creep rate significantly. Moreover, the creep strain for the alloys after 100 hours decreased from 5.2% for Mg–5Al–1Zn–1Si to 2.6% for SJTU-HM1, even lower than that of AE42 (2.7%). It showed that tensile creep property of the newly developed SJTU-HM1 alloy is better than that of AE42 alloy, which is the benchmark creep-resistant magnesium die casting alloy for automobile powertrain application.

3.6 Corrosion resistance properties

Figure 6 shows the salt spray corrosion test result of the alloys. Si shows an adverse effect on corrosion properties. Single addition of Sb shows a similar effect like Si. On the other hand, with both additions of Sb and MM microaddition, SJTU-HM1 shows higher corrosion resistance than those of AZ51 and AE42 alloys. This showed that Misch metal (Ce, La, Nd, Pr) improved the corrosion resistance for Mg–Al based alloys in chloride solutions. The solubility of rare earths in the magnesium matrix is limited in the presence of aluminum, but the intermetallic Al-RE phase formed is electrochemically passive and does not affect the corrosion rate much.8) The high corrosion resistance of the STJU-HM1 appears to be related to a certain positive synergism of aluminum and RE elements in the aluminum rich zones along the grain boundaries, impeding the propagation of localized corrosion attack. The improved passivity of SJTU-HM1 under the conditions is possibly due to the enrichment of trace amounts of RE in the oxide film. Further investigation is under way.

4. Summary

Microstructure and mechanical properties and corrosion resistance for the developed SJTU-HM1 alloy were investigated and summarized as follows:

(1) Addition of Sb was found to be efficient in refining the microstructure of the Mg–5Al–1Zn–1Si-base alloy. The morphology of Mg5Si particles changed from coarse Chinese-script shape to small polygonal type. The modification mechanism of Sb is the formation of the polygonal type Mg5Si particles nucleate from Mg3Sb2 particles.

(2) Refined microstructure in the modified alloy by simultaneous additions of Sb and mischmetal results in significant improvement in tensile properties and toughness, creep resistance at high temperatures as compared to the base alloy of Mg–5Al–1Zn–1Si. The mechanical properties at room temperature are similar to or better than those of AZ91 alloy and the high temperature properties are even better than those of AE42 alloy.

(3) With simultaneous additions of Sb and mischmetal, the corrosion resistance of the Si-containing Mg alloy is improved significantly and even better than that of AE42 alloy.
