Keywords: Multistage martensitic transformation; Ti3Ni4 precipitate; Heat treatment atmosphere; Heterogeneous precipitation

1. Introduction

Ti-Ni alloys of the near-equatomic composition are technologically important materials with their superior shape memory and superelastic properties associated with B2 to R-phase and B19' martensitic transformations. The application of the alloys has been spread to not only engineering but also medical and dental fields. It is widely recognized that improvements of shape memory and mechanical properties in the alloys are achieved by thermomechanical and aging treatment. Especially, the aging treatment is an effective process in Ni-rich Ti-Ni alloys due to precipitation strengthening of the parent phase with coherent Ti3Ni4 phase. It has been known that the aging treatment induces the R-phase transformation. In addition to the generation of R-phase transformation, it has been also reported that the multistage martensitic transformation appears in the aged Ni-rich Ti-Ni alloys. Three mechanisms of multistage transformation have been proposed recently. Khalil-Allafi et al. have explained it on the basis of evolving Ni concentration profiles between particles and differences in nucleation barriers between R-phase and B19' martensitic phase. The latest report of Khalil-Allafi et al. has pointed out that the above two mechanisms cannot rationalize the multistage transformation, and thus the heterogeneity in precipitation morphology of Ti3Ni4 phase is responsible for the multistage transformation from TEM observations. We do not intend to argue against those proposed mechanisms, because they have been discussed self-consistently within each experimental condition. However, some of the present authors have experienced that the multistage transformation is remarkably influenced by heat-treatment conditions, especially heat-treatment atmosphere. The homogeneity in precipitation morphology of Ti3Ni4 phase has been also reported in several articles. We consider that the homogeneity in precipitation morphology is quite natural, since the atomic arrangement of Ti3Ni4 phase are a slight modification of the B2 type superstructure of matrix. On the contrary, Filip and Mazanec have reported recently that aging of fully annealed, defect free materials results in heterogeneous grain boundary precipitation of Ti3Ni4 phase. Khalil-Allafi et al. have reconfirmed the heterogeneous grain boundary precipitation. They have also reported that the heterogeneous grain boundary precipitation is no longer observed when the aging is performed in the presence of external stresses as small as 2 MPa. Therefore, it is worth to reexamine the precipitation behavior of Ti3Ni4 phase in regard to the multistage martensitic transformation.

The purpose of the present study is to clarify experimentally whether the multistage martensitic transformation associated with the heterogeneity in precipitation morphology of Ti3Ni4 phase is an intrinsic nature or an extrinsic one in the aged Ni-rich Ti-Ni alloys.

2. Experimental Procedure

Ti-50.6 at%Ni alloy was prepared from 99.7 mass% sponge Ti and 99.9 mass% electrolytic Ni by a high-frequency vacuum induction furnace using a graphite crucible, followed by casting into an iron mold. The ingot was hot-forged and cold-drawn to rod of 3 mm in diameter. The rod was cut into disks of about 1 mm in thickness for DSC measurements and about 0.2 mm in thickness for TEM observations, respectively. Half of the disks were solely sealed in an evacuated quartz tube of 2.5 × 10⁻³ Pa as shown in Fig. 1(a), which is referred to as condition A hereinafter. The rest were sandwiched between Ti-Ni sheets of the same chemical composition. Subsequently, they were wrapped with pure Ti foil of 200 μm in thickness and then sealed in an evacuated quartz tube of 2.5 × 10⁻³ Pa as shown in Fig. 1(b),
which is referred to as condition B hereinafter. They were solution-treated at 1273 K for 3.6 ks, and then quenched into ice water. Subsequently, the specimens were aged at 773 K for various periods, and then quenched into ice water. For instance, the specimen A-A described in the later section indicates that both the solution treatment and the aging are carried out in the condition A. In addition to conditions A and B, conditions C to G described later were appended. The specimens obtained by various heat treatment conditions were lightly mechanically and chemically polished to remove the surface scale. DSC measurements were performed by using a Shimadzu DSC-50 calorimeter with cooling and heating rate of 10 K/min. TEM specimens were electro-polished using the twin jet method in an electrolyte of 20% H$_2$SO$_4$ and 80%CH$_3$OH in volume around 270 K. TEM observations were carried out in the JEOL-2000FX microscope operated at 200 kV.

3. Results and Discussion

3.1 Effect of heat treatment atmosphere

Figures 2(a) and (b) show DSC cooling curves of the solution treated specimens with the conditions A and B, respectively. There is no difference between the two DSC curves essentially. However, drastic change takes place in the aged specimen as follows. Figures 3(a) and (b) show DSC cooling curves of the specimens A-A and B-B aged at 773 K for various periods, respectively. The first peak denoted as R, which corresponds to the B2 to R-phase transformation, can be seen in all the curves except for the specimen A-A aged for 180 ks. It is notable that the multistage martensitic transformation peaks denoted as M$_1$ and M$_2$ are clearly separated in the specimens A-A except for the specimen aged for 180 ks as shown in (a). On the other hand, there are no multistage martensitic transformation peaks in all the DSC curves in the specimens B-B as seen in (b). The changes of DSC peak temperatures of the specimens A-A and B-B in Figs. 3(a) and (b) are summarized in Figs. 4(a) and (b), respectively, as a function of aging time in a linear logarithm plot. The R in both the specimens is almost constant from the early stage of aging and increases slightly with increasing aging time. The similar tendency has been previously reported in many articles.$^4,6,8,13,15,22$ Although the typical microstructures in A-A and B-B specimens are discussed later, the R is considered to be independent of microstructure changes such as size and dispersion density of Ti$_3$Ni$_4$ precipitates as reported so far. The M$_1$ in A-A specimens linearly increases with increasing logarithm of aging time. It is mainly due to the decrease of Ni concentration in the transformation region. On the other hand, the M$_2$ is constantly low up to aging time of 36 ks, besides the peak area indicated in Fig. 2(a) decreases, and then abruptly increases after prolonged aging period. The M in B-B specimen aged for 3.6 ks slightly decreases, which is due to precipitation of coherent fine Ti$_3$Ni$_4$ particles. Such particles obstruct the shape change for the martensitic transformation. As increasing aging time the particles grow and the effect of Ni depletion in matrix becomes dominant, and thus the M linearly increases.

Subsequently, DSC measurement in specimens A-B and B-A aged at 773 K for 7.2 ks is carried out to confirm a controlling factor in the multistage martensitic transformation. It is apparent that there is multistage martensitic transformation in the specimen A-B in Fig. 5(a), although the feature of DSC curve is quite different from that in the specimen A-A aged at 773 K for 7.2 ks in Fig. 3(a). On the
other hand, a single stage martensitic transformation is
recognized in the specimen B-A as shown in Fig. 5(b). The
feature of DSC curve and transformation temperatures are
almost the same as those in the specimen B-B in Fig. 3(b).
These phenomena indicate that the controlling factor of the
multistage martensitic transformation is the solution treat-
ment condition. It is considered that a kind of compositional
fluctuation is induced during the solution treatment with
condition A and is emphasized during the aging treatment.
Although the mechanism and process of compositional
fluctuation during heat treatment have not been clarified
yet, it may be related to the evaporation of Ti and Ni, the
preferential oxidation of Ti and so on. The precise analytical
method is required to confirm this hypothesis. It is now under
study and will be reported in due course.

In order to establish the further evidence experimentally,
the specimens were heat treated under various conditions as
illustrated in Fig. 6. The specimen is simply sandwiched
between Ti-Ni sheets with the same composition in an
evacuated quartz tube, which is referred to as the condition C.
The condition D indicates that the specimen is sandwiched
between Ti-Ni sheets with the same composition and then
wrapped with Ni foil in an evacuated quartz tube. The
specimen is evacuated with pure titanium block in the
condition E. The condition F indicates that the specimen is
sandwiched between Ti-Ni sheets with the same composition
and then evacuated with pure Ti block in a quartz tube. In the
condition G, the specimen is sandwiched between Ti-Ni
sheets with the same composition and then evacuated with
pure Zr block in a quartz tube. The specimens F-F and G-G
aged at 773 for 7.2 ks only show the single stage martensitic
transformation and the rest show the multistage transforma-
tion. From these results one can imagine that the sandwiched
Ti-Ni plates prevent the evaporation of Ti and Ni and/or the
preferential oxidation of Ti in the specimen, and Ti and Zr
blocks act as a getter material to purify the atmosphere in the
evacuated quartz tube. It can be concluded that the multistage
martensitic transformation is suppressible with the preven-
tion of evaporation of Ti and Ni and/or preferential oxidation
of Ti in the specimen, and the purification of atmosphere in
the evacuated quartz tube. Both factors for the regulation of
atmosphere are indispensable for suppressing the multistage
martensitic transformation.
3.2 Precipitation morphology of Ti$_3$Ni$_4$

In order to obtain the microstructural aspects of each specimen, TEM observations were carried out. Figures 7(a) and (b) show the bright field image of solution treated specimen with the conditions A and B, respectively. No difference between the two images can be recognized on the conventional TEM scale. The average grain size of both the specimens is estimated to be about 40 µm. Figures 8(a) and (b) show the microstructure, respectively, at grain boundary and interior of the same grain in specimen A-A aged at 773 K for 3.6 ks. The size of Ti$_3$Ni$_4$ precipitate at the grain interior about 20 µm away from boundary is about ten times larger than that at the grain boundary, while the precipitation density at the interior is lower than that at the boundary. The correspondence between M$_1$, M$_2$ and those transformation areas such as grain boundary or interior has not been clarified yet. However, since the martensitic phase has been occasionally observed at grain boundary after jet polishing around 270 K, the transformation area of M$_1$ and M$_2$ may correspond to the grain boundary and interior, respectively. On the other hand, homogeneity in distribution and size of precipitates is observed at grain boundary and interior of the same grain in specimen B-B aged at 773 K for 3.6 ks as shown in Figs. 8(c) and (d), respectively. It is recognized that Ti$_3$Ni$_4$ precipitate has the tendency of homogeneous nucleation in TiNi B2 matrix. It is due to similarity of atomic arrangement between TiNi B2 and Ti$_3$Ni$_4$ rhombohedral phases as mentioned above. Although we do not reproduce electron micrographs in A-B, B-A, C-C, D-D, E-E, F-F and G-G specimens aged at 773 K for 3.6 ks here, the microstructure in the specimen A-B is essentially similar to that in the specimen A-A. The microstructure in B-A, F-F and G-G is similar to that in the specimen B-B. In the rest specimens heterogeneous grain boundary precipitation and homogeneous one were randomly observed. Further details will be reported in due course together with the correspondence between M$_1$, M$_2$ and those transformation areas as mentioned above. These results demonstrate that the precipitate morphology is drastically changed with heat treatment atmosphere, especially with solution treatment condition. Consequently, the appearance of multistage martensitic transformation associated with heterogeneous precipitation of Ti$_3$Ni$_4$ is controlled with heat treatment atmosphere. We can finally conclude that the multistage martensitic transformation in aged Ni-rich Ti-Ni alloys is an extrinsic nature, i.e., a kind of artifact during the heat treatment.

In the present study we only investigate the aging of fully annealed, defect free materials. The multistage martensitic transformation has also been observed in the aged specimen after deformation. Since it is likely that the solution treatment atmosphere prior to deformation was not carefully regulated in the previous works, it should be reinvestigated with respect to the heat treatment atmosphere. However, it is difficult to regulate the heat treatment atmosphere from the industrial point of view. Therefore, further understanding of the multistage martensitic transformation mechanism is also required, although the transformation is an extrinsic nature, i.e., a kind of artifact during the heat treatment. Experimentally unsolved questions derived from the present study are listed as follows. The compositional fluctuation between grain boundary and interior upon solution treatment under normal atmosphere such as the condition A-A should be estimated with aid of analytical TEM, Auger electron spectroscopy and so on. Then the heterogeneous nucleation and growth mechanism of Ti$_3$Ni$_4$ phase should be discussed on the basis of compositional

![Fig. 7 Bright field image of solution treated specimen with the conditions (a) A and (b) B.](image-url)
fluctuation result. The correspondence between $M_1$, $M_2$ and those transformation areas should be identified with metallographic techniques.

4. Concluding Remarks

In the present study we demonstrate that the appearance and disappearance of multistage martensitic transformation in aged Ni-rich Ti-Ni alloys depend on the heat treatment atmosphere. No multistage transformation occurs when the evaporation of Ti and Ni and/or the preferential oxidation of Ti in the specimen are prevented and the purification of heat treatment atmosphere is achieved. The heterogeneity in precipitation morphology of Ti$_3$Ni$_4$ phase, which is responsible for the multistage transformation, can be suppressed with the regulation of heat treatment atmosphere as mentioned above. We conclude that the multistage martensitic transformation is an extrinsic nature, i.e., a kind of artifact during the heat treatment, in aged Ni-rich Ti-Ni alloys.
