A Smoothing Filter for Misorientation Mapping Obtained by EBSD

Masayuki Kamaya*

Institute of Nuclear Safety System, Inc., Mikata-gun, Fukui 919-1205, Japan

Electron backscatter diffraction in conjunction with scanning electron microscopy is used to assess local misorientation. However, measurement errors cause the distribution of misorientation to be scattered. To reduce the errors in local misorientation identification and obtain a smooth map, a data processing procedure is proposed. By taking the average of the crystal orientation of surrounding points, the distribution of the local misorientation became smoother and clearer. Moreover, the obtained local misorientation was shown to be valid for quantitatively evaluating the degree of plastic strain induced in Type 316 stainless steel. [doi:10.2320/matertrans.MAW201005]

Keywords: electron backscatter diffraction, crystal orientation, misorientation, filter, plastic strain

1. Introduction

Electron backscatter diffraction (EBSD) in conjunction with scanning electron microscopy is one of the most promising techniques to measure crystal orientation. By using commercial systems for EBSD measurement, we can identify crystal orientations by scanning the surface of samples. Misorientation between neighboring points is a parameter derived from the measured orientation, and is used to quantify the degree of plastic strain induced in a material.1–5) However, the measurement of crystal orientation has an error of 0.1–1° depending on various factors such as the number of pixels of the CCD camera used to capture EBSD patterns,6) parameters for data processing for identifying the orientation from obtained EBSD patterns and the plastic strain.7–9) The magnitude of the error becomes relatively large for a small misorientation.10) Therefore, the misorientation distribution is scattered due to errors when the spatial resolution of the measurements is fine or induced plastic strain is small, and the misorientation map shows a meaningless local variation. For a quantitative evaluation, it is important to reduce the errors and obtain a smooth map.

In this study, a data processing procedure was developed in order to reduce the errors and to exclude the local variation in the misorientation map, then the validity of the proposed procedure for quantifying the plastic strain was examined.

2. Procedure

In general, the averaging of several data is an effective way for reducing the local variation due to errors in measurement. However, the averaging of misorientation does not always reduce the errors, even though it may provide a smooth map. Figure 1 schematically shows the influence of errors in crystal orientation measurement on the misorientation identification. Since the magnitude of measurement error is random, the identified misorientation shows a local variation even if the distribution of true misorientation is smooth. The local variation can be suppressed by taking the average of the fluctuating misorientation. However, the magnitude of the averaged misorientation is not always as the true misorientation: if the error in the misorientation is larger than the true misorientation, the averaged misorientation becomes larger than the true misorientation, because the misorientation angle is an absolute value. Even if true misorientation is zero, averaged misorientation can not be zero no matter how many points are averaged, although the distribution becomes smooth. In particular, to reduce the error in misorientation is important for measurements of high spatial resolution because the misorientation decreases and the error become relatively large.

In order to achieve both smoothing and reduction of errors, in this study, not the misorientation but the measured crystal orientation was averaged. Figure 2 shows a schematic drawing of the averaging procedure. After defining grain boundaries, averages of the crystal orientation of surrounding points are calculated for each point. The number of crystal orientations used for averaging is represented by $\text{ROA}$ (Range Of Averaging). In the case of $\text{ROA} = 3 \times 3$, an average of nine crystal orientations at surrounding points was calculated and the crystal orientation at the center was replaced with the average. The average of 49 points is calculated in the case of $\text{ROA} = 7 \times 7$. When we take the average of the misorientation, the distance from the center should be the same because the magnitude of the misor-
orientation depends on the distance. On the contrary, the distance has minor influence on the averaging in the current procedure and it is possible to take the average of a relatively large number of points from the same area. The averaging is done for the points that exist in the same grain, and a set of quaternion is used for the averaging calculation. In this study, this procedure is referred to as the smoothing filter.

3. Results

The observed samples were strained Type 316 austenitic stainless steel, which was deformed by a tensile load. The material had an approximately equiaxial grain structure with an average grain diameter of 50 μm. Induced macroscopic plastic strain (hereafter, global plastic strain) was \( \varepsilon_p = 0\% \), 4.9\%, 10.3\% and 15.2\%. Details of the procedure of specimen preparation are described elsewhere.

Figure 3 shows the local misorientation, \( M_L \), calculated by the following equation:

\[
M_L(p_o) = \frac{1}{4} \sum_{i=1}^{4} \beta(p_o, p_i)
\]  

where \( \beta(p_o, p_i) \) denotes the misorientation between a fixed point \( p_o \) and neighboring points \( p_i \) in the grain as shown in Fig. 4. Misorientations larger than 5° were regarded as grain boundaries. The spacing between measurements (step size) was \( d = 0.5 \mu m \), and the plastic strain was \( \varepsilon_p = 4.9\% \). By applying the smoothing filter, the local variation in the local misorientation disappeared and the distribution became smooth. Figure 5 shows the change in the local misorientation along a straight line, which crosses grain boundaries. The distribution of misorientations was inhomogeneous and tended to be large near some grain boundaries. Due to the errors in measured crystal orientation, the local misorientation without the smoothing filter was scattered significantly, but was suppressed when the smoothing filter was applied.

Furthermore, the magnitude of the filtered local misorientation was relatively small, which implies that the smoothing filter reduced the error in the crystal orientation. It should be noted that the averaging cuts down peaks in local misorientation. Therefore, the spatial resolution of the mapping may deteriorate by the filtering.

Figure 6 shows the local misorientation obtained under different measurement condition; the number of pixels of the CCD camera for EBSD pattern acquisition was 640 \times 480 (hereafter, “fine pixel”) whereas it was 128 \times 96 (hereafter, “coarse pixel”) in Fig. 3. The fine pixel CCD camera condition makes it possible to measure precise crystal orientation and reduces the local variation in the local misorientation. In spite of such significant difference in the local misorientation map, the maps after applying the smoothing filter showed similar distribution.

In order to assess the effect of the filtering, the average of the local misorientation, \( M_{ave} \), was calculated by the following equation:

\[
M_{ave} = \exp \left[ \frac{1}{N} \sum_{i=1}^{N} \ln[M_L(p_i)] \right]
\]
where $N$ is the number of data included in the map. Only grains consisting of more than 10 points were included in the calculation; smaller grains were ignored. The local misorientation distribution was well-represented by the log-normal distribution. The change in averaged local misorientation with ROA is shown in Fig. 7. $M_{\text{ave}}$ decreased by applying the smoothing filter, due to the reduction of the errors included in the misorientation. The magnitude of $M_{\text{ave}}$ was almost the same under the coarse pixel and the fine pixel conditions when the smoothing filter was applied. Figure 8 shows the local misorientation distributions for larger degree of ROA. A large ROA reduces $M_{\text{ave}}$ not only by eliminating errors but also by cutting down peaks in local misorientation distribution. For a quantitative evaluation, it is important to get the same results from different measurements conditions under the same step size. The agreement of $M_{\text{ave}}$ from the coarse pixel and fine pixel conditions implies that the smoothing filter works well to reduce the error and enables us to compare the results from different measurement conditions.

### 4. Effect on Quantitative Evaluation

In the previous study, it was shown that the averaged local misorientation $M_{\text{ave}}$ was correlated with the plastic strain $\varepsilon_p$, showing linear correlation at less than $\varepsilon_p = 15\%$. This correlation was evaluated using the filtered data. Figure 9 shows the relationship between $\varepsilon_p$ and $M_{\text{ave}}$ for
different step size of $d$. The averages of $M_{ave}$ from four maps, whose size was 250 µm x 250 µm, were shown and the error bars denotes the maximum and minimum values. The solid line shows the correlation obtained by a linear regression and expressed by:

$$M_{ave} = (-0.0062 d^2 + 0.037 d) \varepsilon_p + 0.05$$  \hspace{1cm} (ROA = 3 \times 3)  \hspace{1cm} (3)$$

$$M_{ave} = (-0.0029 d^2 + 0.042 d) \varepsilon_p + 0.15$$  \hspace{1cm} (without filtering)  \hspace{1cm} (4)$$

where the strain is given in percent and step size in µm. $M_{ave}$ shows an excellent correlation with the plastic strain regardless of the filtering. However, the variation of $M_{ave}$ for each sample is smaller for the filtered data. It is deduced that the error in measurements caused the relatively large variation in $M_{ave}$ in the unfiltered data. Agreement of $M_{ave}$ at strain of 0% from different step sizes implies that $M_{ave}$ of unstrained sample does not emanate from residual plastic strain but from inherent fluctuation in crystal orientation and unresolved background error. Since the misorientation can not be less than the magnitude of error, average error in local misorientation identification is less than 0.05°, which is $M_{ave}$ of unstrained sample. The magnitude of error was improved from 0.15° by the filtering.
The size of 250 μm × 250 μm seems to be large enough for representing the local inhomogeneity of the plastic strain if the error in measurement is excluded. By using eqs. (3) and (4), it is possible to quantify the magnitude of local plastic strain.

5. Conclusions

In order to reduce the fluctuation in the local misorientation and to obtain a smooth map, a data processing procedure was proposed. By taking the average of the crystal orientation of surrounding points, the distribution of the local misorientation became smooth and clear. Average error in local misorientation identification is suppressed to less than 0.05° by the filtering. Moreover, the obtained local misorientation was shown to be valid for quantitatively evaluating the degree of plastic strain induced in Type 316 stainless steel. The smooth filtering improves the accuracy of estimation of the global plastic strain.
