A new sensing method called “smart stress-memory patch” has been proposed for fatigue damage evaluation of structures. This patch estimates the number of cycles and stress amplitude using its crack length. In this study, fatigue crack growth behavior in thin pure copper sheet was investigated under strain-controlled testing to evaluate the sensor characteristics when the patch is attached to structure. Electrodeposited (ED) copper of 99.96\% purity with an average grain size of 2 µm provided a stable crack propagation and easy observation of crack length. The relationship between stress intensity factor range and crack growth rate was fitted on one curve regardless of strain amplitude. The scattering in fatigue crack growth was evaluated by a stochastic model, and it demonstrated that the error of fatigue cycles estimated by the patch is small enough. Furthermore, stress transfer between the patch and structure was calculated on the simple assumption that the patch is perfectly bonded on the structure, and it was shown that the patch attached to structure can estimate the number of cycles and stress amplitude on the structures.

Keywords: fatigue crack growth, strain-controlled testing, electrodeposited copper, fatigue sensor, structural health monitoring

1. Introduction

Structural health monitoring (SHM) is highly required to ensure the reliability of bridges, ships, trains, aircraft, power plants and industrial machines. Especially, a long-term sensing method of fatigue damage is very important to avoid the fracture caused by cyclic loading. Strain gauge, FBG (Fiber Bragg Grating) sensor1,2 and wireless strain sensing systems3–6 are utilized to monitor strain and to evaluate fatigue damage. However, there are several problems on the practical use such as necessity of wiring, electrical power supply and complicated measuring devices. Concept of smart stress-memory patch (hereinafter called “smart patch”) was proposed to overcome above problems in the previous papers.7–12 Sensor in smart patch consists of a thin metal sheet with a pre-crack, and the number of fatigue cycles and stress amplitude on structure can be estimated from fatigue crack growth in the sensor. Smart patch is a promising technique for long-term SHM because it needs neither power supply nor wiring. Furthermore, the patch is successfully applied to batteryless wireless system to measure the crack length in the sensor using RFID (Radio Frequency Identification).12

The fatigue crack growth behavior in the sensor under stress-controlled fatigue test has been investigated to estimate stress amplitude and fatigue cycles.7,8) However, when the patch is attached to structure, the sensor is subjected to strain-controlled loading under the change in strain of the structure. Therefore, it is necessary to evaluate fatigue behavior in the sensor under strain-controlled conditions for application of smart patch to structure. While most studies about fatigue in thin metal sheet have focused on stress-life (S-N) and strain-life (ε-N) curves for reliability of microelectronic products,13–16) the fatigue crack growth behavior under strain-controlled testing has not been enough explored in detail.

In this article, fatigue crack growth behavior of the sensor (thin pure copper sheet) was evaluated under uniaxial strain-controlled fatigue testing in order to obtain the characteristics of the attached sensor to structure. The scattering in crack growth was also examined by a stochastic model to assess the error in estimation of fatigue cycles and stress amplitude. From these observations, a method to evaluate fatigue cycles and residual fatigue life of structure using smart patch was proposed.

2. Principle of Smart Stress-Memory Patch

The details of the principle were described in the previous paper.7) A schematic image is shown in Fig. 1(a). Sensor in the patch consists of a thin metal sheet with a pre-crack. Since fatigue damage in structure tends to occur in structural component, more than one sensor is attached, for example, close to the welded part. When the structure is subjected to cyclic loading, the sensor is also cyclically loaded in response to the change of strain in the structure. Then, fatigue crack growth from pre-crack in the sensor will occur according to the cyclic loading. After a certain period, the crack length in each sensor will be measured by optical microscope or wireless measurement of electrical resistance change. The number of fatigue cycles (N) and stress amplitude (Δε) on the structure can be estimated from the crack length detected from two sensors with different characteristics as shown in Fig. 1(b).

3. Experimental Procedure

3.1 Materials

The sensor was made of electrodeposited (ED) copper of 99.96\% purity with an average grain size of 2 µm because of its good corrosion resistance and easily observation of the crack length. This small grain size provides stable crack propagation. The ED copper sheet with a thickness of 0.1 mm was cut to rectangular coupons with a dimension of 40 mm × 5 mm. A single notch with a length of 2.5 mm and a width of 0.3 mm was induced at the center from one side of the coupon. The notch tip was a round shaped with a

*Graduate Student, The University of Tokyo
radius of approximately 150 µm. Additionally, the notch tip was sharpened to curvature radius of about 30 µm by the blade (High-stainless 100 µm, Feather Safety Razor Co., Ltd.). One side of the coupon was polished to a mirror finish using 3 and 1 µm alumina slurry to observe crack length clearly. Afterward, fatigue pre-crack was introduced until total crack length reached to about 2.7 mm.

3.2 Fatigue test

Both ends of the sensor were clamped in jigs mounted in a fatigue testing machine (MMT-100N, Shimadzu), and the gauge length between the upper and lower jigs is adjusted to 20 mm. Fatigue tests were performed under maximum crosshead displacement ($u_{\text{max}}$) of 20, 25 and 30 µm, displacement ratio of $R = 0.1$ and frequency of 19 Hz. Given that strain is defined as a crosshead displacement divided by gauge length of specimen, strain ratio is $R = 0.1$ and maximum strain ($\Delta \sigma$) is 0.10, 0.125 and 0.15%, respectively. Change in crack length as a function of the number of fatigue cycles was monitored optically with digital microscope (VHX-600, Keyence). The tests were conducted two times under each condition to evaluate the reproducibility and the scattering in fatigue crack growth.

4. Analytical Procedure

4.1 Finite element analysis of stress intensity factor

A proper shape factor ($f(\alpha)$) for the present sensor geometry is necessary to characterize the fatigue crack growth behavior as a function of stress intensity factor range ($\Delta K$). It is commonly known that the stress intensity factor ($K$) of single edge-cracked tension specimen with prescribed end displacements can be expressed by

$$K = \sigma \sqrt{\pi a} \cdot f(\alpha, \beta), \quad \sigma = \frac{E}{1 - \nu^2} \cdot \frac{u}{L}$$

$$\alpha = \frac{a}{W}, \quad \beta = \frac{L}{W}$$

(1)

where $W$ is width of the specimen, $L$ is gauge length of the specimen, $a$ is crack length, $E$ is Young’s modulus, $\nu$ is Poisson ratio, $u$ is displacement on the specimen, $\alpha$ is normalized crack length and $\beta$ is ratio of the gauge length to the width.\(^{(17)}\) Although the shape factor has been investigated in the range of $\beta = 0.5$ to $3$,\(^{(18)}\) the present sensor has the higher value of $\beta = 4.0$ ($L = 20$ mm, $W = 5$ mm).

In order to evaluate shape factor of the sensor ($\beta = 4.0$), linear elastic stress analysis was performed by finite element method (FEM). Geometry and boundary conditions for the simulation are shown in Fig. 2, where $L$ was 20 mm, $W$ was 5 mm, Young’s modulus was 120 GPa, Poisson ratio was 0.34 and $u$ was changed from 2 to 30 µm in the same as experimental conditions. The model was sectioned into quadrilateral plane stress elements with size of 0.05 mm $\times$ 0.05 mm. In the analysis, ten integration paths were defined from the crack tip to the outside, and the $J$-integral was calculated for normalized crack length ($\alpha = a/W$) ranging from 0.1 to 0.9. Since the $J$-integral reached a constant value from the fifth path in each condition, the constant value was used for calculation of stress intensity factor. Under plane stress conditions, the stress intensity factor can be described by

$$J = K^2/E$$

(2)

and the shape factor was systematically solved using eqs. (1) and (2) for the above range of crack length.

4.2 Stochastic analysis of fatigue crack growth

It is significant to evaluate the scattering in fatigue crack growth in the sensor because the error in estimation of fatigue cycles and stress amplitude from crack length becomes larger with the scattering. Scattering of this copper
sensor under stress-controlled fatigue test has been investigated using a stochastic model. In this model, a random variable \( Z \) is introduced to Paris law as the following equations:

\[
\frac{da}{dN} = Z \cdot C(\Delta K)^m
\]  

\( (3) \)

where \( da/dN \) is crack growth rate and \( C \) and \( m \) are materials constants. If \( \log Z \) follows a normal distribution with zero mean, the probability density function is written by

\[
g(\log Z) = \frac{1}{\sqrt{2\pi \sigma_{SD}}} \cdot \exp\left(-\frac{(\log Z)^2}{2V}\right)
\]

\( (4) \)

where \( \sigma_{SD} \) is standard deviation and \( V \) is variance of \( \log Z \).

Integrating both sides of eq. (3) from initial normalized crack length \( (\alpha_0) \) to certain crack length \( (\alpha) \), relationship between fatigue cycles and crack length including the scattering was obtained by

\[
N_Z = \frac{1}{Z} \cdot \frac{W}{C} \int_{\alpha_0}^{\alpha} \Delta K^{-m} d\alpha
\]

\( (5) \)

where \( N_Z \) is fatigue cycles including scattering. The experimental data obtained in present work were applied to the above stochastic model, and statistical properties of \( \log Z \) were evaluated to predict the crack growth process including the scattering.

5. Results and Discussion

5.1 Fatigue crack growth

Fatigue crack path of the sensor exhibited the significantly straight line as shown in Fig. 3. It allows us to measure the crack length easily. Figure 4 shows relationships between the number of fatigue cycles and crack growth rate calculated by the incremental polynomial technique under each test condition. Tests performed two times under the same condition showed good repeatability. The crack growth rate was almost constant with fatigue cycles in the range of \( a = 2.7 \text{ mm} \) to \( 4 \text{ mm} \) under low strain amplitude, and it slightly decreased with fatigue cycles especially at maximum strain of \( 0.15\% \). This tendency is quite different from that of the stress-controlled fatigue behavior.

5.2 Stress intensity factor

Shape factor for the present sensor geometry was calculated by FEM to examine the fatigue crack growth characteristics as a function of stress intensity factor range, as shown in Fig. 5. Shape factor of function of \( \alpha \) can be fitted as follows:

\[
f(\alpha) = 1.01 - 0.11\alpha + 3.39\alpha^2 - 8.12\alpha^3 + 4.57\alpha^4.
\]

\( (6) \)

Relationship between stress intensity factor range calculated by the above equation and crack growth rate under each experimental condition are shown in Fig. 6. It can be fitted on Paris equation as:

\[
\frac{da}{dN} = C(\Delta K)^m, \quad \Delta K = (1 - R)K_{max}
\]

\( (7) \)

where \( m = 3.91 \) and \( C = 5.85 \times 10^{-13} \) and \( K_{max} \) is the value of stress intensity factor at \( \nu = u_{max} \). The correlation coefficient was 0.980. Therefore, it was shown that the relationship between stress intensity factor range and crack growth rate can be expressed by one curve regardless of strain amplitude under strain ratio of \( R = 0.1 \).
5.3 Scattering in fatigue crack growth

In order to evaluate the scattering in fatigue crack growth, Log $Z$ was calculated from eq. (3) for each experimental data as shown in Fig. 7. In these figures, mean value $(\mu)$ is almost zero and standard deviation $(\sigma_{SD})$ is smaller than rolled Cu ($\sigma_{SD} = 0.13–0.17\%$). It demonstrates that the scattering of ED Cu is small compared with rolled Cu. Log $Z$ of all data are also plotted on a normal distribution sheet as shown in Fig. 8. They are well fitted by straight line, therefore, it is confirmed that log $Z$ follows to a normal distribution with zero mean.

5.4 Evaluation of fatigue damage

Based on fatigue testing results, a method to evaluate fatigue damage of structure using smart patch will be discussed.

5.4.1 Attachment to structure

When the patch is attached to structure, the sensor is subjected to strain-controlled loading under the change in stress intensity factor range, $\Delta K / \text{MPa} \cdot \text{m}^{1/2}$.
strain of the structure. A simple model for the attached sensor to structure is depicted in Fig. 10. It is assumed that the far-field stress in the plate is a uniaxial tension ($\sigma_{\text{structure}}$) in elastic region and the sensor is perfectly bonded on the plate. If thickness of the sensor is enough thin, strain distribution in the plate is uniform regardless of the presence of the sensor, and $\sigma_{\text{structure}}$ is described as follows:

$$\sigma_{\text{structure}} = E_{\text{structure}} \frac{u}{L}$$  (8)

where $E_{\text{structure}}$ is Young’s modulus of structure, $u$ is the displacement on the sensor and $L$ is gauge length of the sensor, respectively. In the following sections, a method to estimate fatigue damage parameters will be proposed in the case that the structure is subjected to cyclic loading with the stress ratio ($R = \sigma_{\text{structure,min}}/\sigma_{\text{structure,max}}$) of 0.1, material of which is steel ($E_{\text{structure}} = 200$ GPa).

5.4.2 Estimation of fatigue cycles

Since strain ratio of the attached sensor is also 0.1 in the above case, the fatigue crack growth behavior in the sensor can be predicted from the results as shown in Fig. 9. Substituting eq. (8) to eqs. (1) and (5) with log $Z = 0$, fatigue cycles can be expressed as:

$$N = \frac{W}{C} \left( \frac{\Delta \sigma_{\text{structure}} E_{\text{sensor}}}{(1 - R) E_{\text{structure},\text{max}}} \right) \int_{\alpha_0}^{\alpha} (\sqrt{\sigma_i f(\sigma_i)})^{-m} d\alpha_i$$

$$\Delta \sigma_{\text{structure}} = (1 - R) \sigma_{\text{structure},\text{max}}$$  (9)

where $E_{\text{sensor}}$ is Young’s modulus of the sensor. The effect of scattering is not considered in this equation. Fatigue cycles were calculated by eqs. (6) and (9) as a function of stress amplitude ($\Delta \sigma_{\text{structure}}$) and normalized crack length in the sensor, as shown in Fig. 11. Stress amplitude can be estimated from crack length detected from two sensors with different characteristics, as the details were described in the previous paper. Therefore, it was shown that fatigue cycles on structures can be estimated using smart patch.

5.4.3 Estimation of residual fatigue life

Evaluation of residual fatigue life of structure is important to avoid the rapture caused by cyclic loading. Residual fatigue life ($N_r$) is commonly defined as:

$$N_r = N_f - N$$  (10)

where $N_f$ is a number of cycles to failure. Based on many studies about fatigue life of structural components, relationship between stress amplitude and the number of cycles to failure is generally characterized by S-N curve in high-cycle fatigue situations as:

$$N_f = C_{\text{SN}} \Delta \sigma^{-m_{\text{SN}}}$$  (11)

where $C_{\text{SN}}$ and $m_{\text{SN}}$ is material constants and $\Delta \sigma$ is stress amplitude. For example, S-N curve of general structural steel with $m_{\text{SN}} = 3$ and the fatigue strength at two million cycles (FAT) of 100 MPa is shown in Fig. 12. Substituting fatigue cycles ($N$) in the previous section (Fig. 11) to eqs. (10) and (11) with $m_{\text{SN}} = 3$ and FAT of 100 MPa, the residual fatigue life can be calculated as a function of stress amplitude and normalized crack length in the sensor, as shown in Fig. 13. It was demonstrated that residual fatigue life can be estimated from stress amplitude and crack length in the sensor. As shown in the figure, the structure is safe when the stress amplitude is low and the crack length is small. Since this patch needs neither power supply nor wiring, these results are significant for a long-term monitoring of fatigue damage of structure.
6. Conclusions

Fatigue crack growth behavior in thin pure copper sheet with pre-crack was evaluated under strain-controlled fatigue testing in order to obtain the sensor characteristics of smart patch and the following conclusions were obtained.

1. Relationship between stress intensity factor and crack growth rate is fitted on one curve regardless of strain amplitude under strain ratio of $R = 0.1$.

2. The scattering in fatigue crack growth was evaluated by a stochastic model, and it demonstrated that the error of estimated fatigue cycles using smart patch is small enough.

3. Based on these fatigue testing results, this new sensing method to evaluate fatigue cycles and residual fatigue life of structure is promising for structural health monitoring.
