In order to examine the effect of threading dislocations on the structure of InGaN/GaN multiple quantum wells (MQWs) grown by metal-organic vapor-phase epitaxy (MOVPE), epitaxial lateral overgrowth (ELO) on a patterned sapphire substrate was employed and the MQWs were characterized as a function of the lateral position in terms of cathode luminescence (CL), transmission electron microscopy (TEM) and scanning transmission electron microscopy (STEM). The intensity of a blue luminescence peak (426 nm) was larger for the epitaxial layer overriding on the masked area, while the peak wavelength was independent of the position. Threading dislocations, which were generated at the GaN/sapphire interface, did not propagate to the surface of GaN layer on the masks. The thicknesses of both the InGaN well and the GaN barrier, on the other hand, were the same for the MQWs both on the unmasked surface and on the masks, which is consistent with the invariable peak wavelength of the blue luminescence. For an InGaN well with the indium content of around 10%, it seems that the existence of threading dislocations does not affect the structure of the MQWs but just reduces the luminescence intensity through a recombination via mid-gap states. Keywords: InGaN, multiple quantum wells (MQWs), metal-organic vapor-phase epitaxy (MOVPE), epitaxial lateral overgrowth (ELO)

1. Introduction

There is an increasing demand for solid-state lighting using light-emitting diodes (LEDs). InxGa1−xN is a promising material for the active medium of LEDs because the bandgap of InxGa1−xN varies from 0.65 to 3.6 eV as a function of an indium content x, which covers from infrared to ultraviolet wavelength range. InGaN is also free from hazardous elements.

Growth of InxGa1−xN has confronted a lot of difficulties. Since an InxGa1−xN layer is typically grown on a GaN underlayer, there is compressive strain on the InxGa1−xN layer which arises difficulties in both the coherent growth of the InxGa1−xN and the incorporation of indium by a large amount. Due to this strain, it is difficult to grow a thick InxGa1−xN layer with a uniform indium content. Instead, multiple quantum wells (MQWs) containing thin (a thickness of 1–10 nm) InxGa1−xN layers are commonly used. MQWs are also beneficial for carrier confinement that increases luminescence intensity.

Along with the difficulty in the growth of InGaN itself, a GaN underlayer has been accompanied by the difficulties in the growth on a foreign substrate. Since the bulk growth of GaN is difficult, GaN layers have been grown on sapphire substrates, which induces numerous dislocations in the GaN layers due to the lattice mismatch between GaN and sapphire. Such dislocations significantly affect the structure of InGaN/GaN MQWs; especially, lateral uniformity of both the thickness and the indium content of the InGaN wells can be deteriorated by the existence of dislocations.1–5) Even if the structure of the MQWs is unaffected by dislocations, transport properties of electrons and holes, which are often clearly manifested in the properties such as luminescence wavelengths and their intensities, can be affected by the existence of dislocations.4)

For the system with a large mismatch between an epitaxial layer and a substrate, epitaxial lateral overgrowth (ELO), in which a crystal layer is grown on a patterned substrate not only to vertical but also to lateral directions, can provide an epitaxial layer without dislocations on the masked area because threading dislocations stemming from the interface between the layer and the substrate do not propagate in the lateral direction.6,7) In other words, the ELO can provide the epitaxial layer that has a significant distribution of the dislocation density in a way that is defined by the mask shape on a substrate.

The aim of this work is to clarify the effect of threading dislocations on the structure and the optical properties of InGaN/GaN MQWs. For this purpose, a GaN template grown by the ELO is desirable because it has a designed distribution in the dislocation density. By the growth of the MQWs on the ELO template, we can obtain the MQWs affected by the threading dislocations and those without such an effect simultaneously, keeping the other conditions exactly the same. For the characterization of luminescence properties, cathode luminescence was employed because it provides spatially-resolved luminescence spectra of a layer with a resolution of approximately 0.1 μm. For the structural characterization of the MQWs, cross-sectional transmission electron microscopy (TEM) was employed. Along with conventional bright-field TEM images, scanning TEM (STEM) was employed to observe the threading dislocations and the structure of MQWs more clearly as decoupled from the contrast due to the strain of a sample.

2. Experimental

2.1 Growth of InGaN/GaN MQWs

For the epitaxial growth of GaN and InGaN, metal-organic vapor-phase epitaxy (MOVPE) was adopted because it is one of the most suitable methods for both the ELO and the growth of MQWs, especially for nitride semiconductors. A 2.3-μm-thick GaN layer was grown by MOVPE on a patterned 2-inch sapphire substrate, yielding a flat template for the growth of the InGaN/GaN MQWs. This template was once cleaved to make smaller test substrates, and then the substrate was introduced to the MOVPE reactor to grow the InGaN/GaN MQWs. The detailed experimental conditions are described below.

A 0.1-μm-thick SiO\textsubscript{2} film was deposited on a (0001) sapphire substrate by sputtering. A line-and-space pattern, consisting of a repetition of a mask and a spacing, was patterned along the \([11\overline{2}0]\) direction of the substrate using photolithography and wet-chemical etching. Since the \([11\overline{2}0]\) direction of GaN is parallel to the \([11\overline{2}0]\) direction of the sapphire substrate, as described later in the section 3.1, the stripe pattern is along the \([11\overline{2}0]\) direction of GaN.

The patterned substrate was introduced to an MOVPE reactor (Aixtron, AIX 200/4 RF-S), and was heated at 1175°C under H\textsubscript{2} flow for thermal cleaning. The growth of GaN started from the low-temperature buffer growth at 550°C and then high-temperature continuous growth was executed for 45 min at 1200°C. The total pressure was 2×10\textsuperscript{4} Pa and the source materials were (CH\textsubscript{3})\textsubscript{3}Ga (TMGa) and NH\textsubscript{3}. The growth of the GaN layer starts from the unmasked sapphire surface, as confirmed by the analysis of initial nucleation, and then the GaN layer grows not only in the vertical direction but also in the lateral direction to form a GaN layer overriding on the masks. This is a typical epitaxial lateral overgrowth (ELO).

The growth of the MQWs consisting of InGaN well and GaN barrier layers were grown in the different growth batch from the underlying GaN template. After the cleaved template was cleaned by H\textsubscript{2}SO\textsubscript{4} and DI water, it was introduced to the same MOVPE reactor and a 3-nm-thick GaN buffer layer, 5 pairs of MQWs consisting of a 3-nm-thick InGaN well and a 17-nm-thick GaN barrier, and a 17-nm-thick GaN cap layer were grown at 800°C, 2×10\textsuperscript{4} Pa. The precursors were (C\textsubscript{2}H\textsubscript{5})\textsubscript{3}Ga (TEGa), (CH\textsubscript{3})\textsubscript{3}In (TMIn) and NH\textsubscript{3} with N\textsubscript{2} carrier. An indium content in the InGaN well was 0.10±0.02 as estimated by the fringes of X-ray diffraction (2θ-ω). The MQWs are not doped.

2.2 Characterization

For the optical characterization of the MQWs, cathode luminescence (CL) (JEOL, JSM-7000F) was used for the measurement of spatially-resolved luminescence. In this measurement, an acceleration voltage was 15 kV, and absorption current was 3×10\textsuperscript{−10} A. Spatial resolution is determined by the diffusion length of a minority carrier and is roughly several ten nanometers. Carbon was sputtered on the surface of the sample to prevent the charge-up.

For the structural characterization, cross-sectional TEM and STEM were adopted. Thin foils for TEM and STEM observation were prepared by the conventional method of grinding, dimpling and finally Ar ion milling. TEM and STEM observation were conducted by a field emission type high resolution TEM (TOPCON, EM-002BF) and a Cs-corrected STEM (JEOL, JEM-2100F), respectively.

3. Results and Discussion

3.1 Epitaxial lateral overgrowth characterized by TEM

Figure 1(a) shows the cross section of the GaN layer on the patterned sapphire. The cross section is perpendicular...
to the stripe mask patterns. The growth of the GaN layer starts on the unmasked sapphire surface and the layer overrides on the mask without voids on it, resulting in a 5.8-μm thick planar layer. The surface of the layer was almost flat, but there sometimes existed pits at the center of the mask where two GaN layers from the both mask edges collide with each other. A selected area diffraction (SAD) pattern taken at the interface between the GaN layer and the sapphire substrate, as shown in Fig. 1(c), indicates that the cross sections are the m-plane (\(1\overline{1}00\)) for the GaN layer and the a-plane (1120) for the sapphire substrate, respectively. Since two diffraction patterns can be clearly observed at the same time, the GaN layer grows epitaxially on the sapphire substrate with a rotation angle of 30°, which is a typical relationship for the epitaxial growth on the c-plane (0001).

On the top of the GaN layer by ELO, 5 periods of InGaN/GaN MQWs were grown successfully on the flat c-plane GaN underlayer, as indicated by the arrows in Fig. 1(b). The spacing of the wells is confirmed to be 20 nm.

### 3.2 Cathode luminescence from InGaN/GaN MQWs and GaN underlayers

Figure 2 shows the top-view scanning electron microscope (SEM) image of the InGaN/GaN MQWs. As shown by the dashed lines, the positions of the mask edges are estimated from the mask pattern and the position of the pits which mostly existed at the center of the masks. Note that the micrometer-scale pits are formed by inadequate coalescence of the layers growing in the lateral direction from the unmasked areas and do not correspond to the position of threading dislocations. The following spatially-resolved cathode luminescence analysis concerns the 81 points as shown in the figure.

Figure 3 shows the cathode luminescence spectra observed at the positions 65 and 75 in Fig. 2, as indicated by the bold arrows. Three typical luminescence peaks were observed: 366 nm for the emission from GaN bulk, 426 nm for the emission from the InGaN well, and 562 nm which is called ‘yellow luminescence’ and is associated with defect states between GaN band edges.\(^8\text{-}^{10}\) The spectrum at the point 65,
which is close to the center of a mask, exhibited a reduced yellow luminescence compared with the point 75 which is on the unmasked sapphire surface. Conversely, the luminescence from the GaN bulk and the InGaN well is stronger at the point 65. This trend is quite consistent with an interpretation that a number of threading dislocations in the layer on the unmasked surface provide mid-gap states that function as radiative recombination centers.

In order to clarify the spatial distribution of the intensities of those peaks, intensity mapping images were taken as shown in Fig. 4. The clearest trend is that the intensity of the yellow luminescence (562 nm) is small at the central part of masks. This is likely to be related to a reduced number of dislocations as described just above. Contrary to the yellow luminescence, the luminescence from the GaN band edges (366 nm) is stronger at the central part of masks, although the contrast is not enough in the figure. In fact, the strongest luminescence at 366 nm is observed at the boundary of pits on the masks, probably because the efficiency of light extraction at the boundary of the pits is larger due to the effect of 3-dimensional shape. The yellow luminescence at 562 nm is also enhanced slightly on the boundary of the pits similarly to the trend of GaN, which can be explained by the same mechanism if we assume that the yellow luminescence comes from the GaN layer. The distribution of the luminescence intensity from the InGaN wells (426 nm) is hardly observed, except for the absence of luminescence at the pits.

Figure 5 shows the luminescence intensities for these three peaks as a function of the position that is shown in Fig. 2. Subtle variation in the intensity is more observable than the mapping images in Fig. 4. There are two trends that are overlapping in the plot;

(a) on the masks (points 9–23, 33–47, 57–68), the intensities at 366 and 427 nm increase while the intensity at 562 nm decreases;

(b) at the center of pits (points 17, 40), all the intensities at three wavelengths decreases.

The trend (a) seems to be related with the decrease in the number of threading dislocations around the center of the masks. For the points 33–47, however, the increase in the intensity at 426 nm seems to be hidden behind the trend (b).

The trend (b) is due to the existence of pits. At the center of
pits, the secondary electron signal is also weak as shown in Fig. 2. The dented shape of these pits seems to prevent the luminescence to reach the detector, resulting in the low intensity at all the wavelengths. The thickness of the InGaN wells is reported to vary significantly when the micro-facets emerge on the surface of the underlying GaN, which shifts the luminescence wavelength from the InGaN wells. It is, therefore, natural that the luminescence at 426 nm disappears not only at the center of the pits but also at the whole area of the pits where micro-facets have emerged. For the points 57–68, where only one small pit exists in the vicinity of the measurement points, the trend (b) is almost negligible and we can clearly observe the trend (a).

As discussed above, the profile of the luminescence intensities indicates that the number of threading dislocations is decreased at the center of the masks, contributing to an increase in the luminescence intensities from both the GaN band edges and InGaN wells. In the present observation, the change in the luminescence from the InGaN wells is limited in its intensity. It has been reported that threading dislocations in the GaN underlayer of the InGaN/GaN MQWs often result in “V-pits”, which locally alter the surface incorporation of In and Ga due to the appearance of (1011) facets and thus deform the structure of the MQWs.1–3 In the present study, the peak position from the InGaN wells was not affected by the existence of threading dislocations, and we did not observe such deformation of the MQWs due to the “V-pits”.

### 3.3 Structural analysis by STEM

In reference to the discussion above, the structural characteristics that we have to clarify are (1) distribution of threading dislocations caused by the existence of the masks on the sapphire substrate and (2) vertical and lateral uniformity of the thicknesses of the InGaN wells and the GaN barriers. In order to clarify these characteristics more clearly, we have employed STEM in a thick area of the foil in order to eliminate the contrast due to the strain of samples.

In the cross sectional STEM-HAADF images in Fig. 6, the distribution of threading dislocations can be clearly seen with white lines. There are a number of threading dislocations in the GaN layer stemming from the GaN/sapphire interface. These dislocations do not propagate to the surface of the layer overriding on the masks. As a result, the GaN underlayer for the InGaN/GaN MQWs has a distinctive distribution of the number of threading dislocations; a significant number of threading dislocations on the unmasked surface while a much reduced number of dislocations on the masks. It is noted that there exists no threading dislocations in the vicinity of the surface of the layer on the masks as in the Fig. 6. It is, therefore, possible to examine the effect of threading dislocations on the optical properties and the structure of InGaN/GaN MQWs as decoupled from the effect of growth conditions, through the comparison between the MQWs on the unmasked and those on the masks. These findings are consistent with the trend of cathode luminescence.

Figure 7 shows the cross sectional STEM-HAADF images of InGaN/GaN MQWs both on the mask and the unmasked sapphire surface. The InGaN layers are seen in the vicinity of the surface by the lines with bright contrast due to Z-contrast effect. The thickness of the InGaN well is 3–4 nm and the spacing is 20 nm regardless of the positions, i.e., the structure of the MQWs is independent of the density of the threading dislocations in the present study. This is consistent with the luminescence peak wavelength from the InGaN wells that was independent of the measurement positions.

### 4. Conclusion

The ELO of the GaN template and the InGaN/GaN MQWs on a patterned sapphire c-plane substrate allows us to
examine the effect of threading dislocations on the structure and the optical properties of the InGaN well, keeping the other conditions exactly the same. On the masks, where no threading dislocation was found in the vicinity of the surface by the STEM observation, the luminescence from the InGaN well, the indium content of which was approximately 10%, was stronger compared with that on the unmasked area. The “yellow luminescence”, which is considered to be due to dislocations, was weaker on the masks than on the unmasked area. The luminescence wavelength from the InGaN well was independent of the position on the surface, and the structure of the well was also independent of the position as confirmed by the STEM observation. Therefore, it seems that the existence of threading dislocations just reduces the luminescence intensity through a recombination via mid-gap states and the structures of the InGaN wells is unaffected by dislocations, for the InGaN wells with relatively low indium content. This conclusion, however, can be limited to the specific range of indium content around 10%, because it has been reported that the behavior of carriers in InGaN is much dependent on indium content.12)
