Commercially pure titanium plates were embedded in mixtures of steel and activated carbon powders and then heated at 1273 K for 3.6 ks in a nitrogen flow. During this simplified treatment, a Ti(C, N) layer with a thickness of approximately 10 µm formed on the titanium surface. The surface hardness of the titanium plates coated with the Ti(C, N) layer was more than HV = 1000 regardless of the steel powder ratio in the mixture. Although a Ti(C, N) layer formed upon heat treatment with the activated carbon powder alone, addition of the steel powder led to an increase in the surface hardness and layer thickness. From X-ray diffraction results, Ti(C, N) began to form on the titanium plate heat-treated at 1073 K and became a complete layer at higher heating temperatures. Instead of activated carbon, the use of graphite with added alumina as a reliable anti-sintering agent had no negative effects on the formation of the Ti(C, N) layer. 1. Introduction

Titanium and its alloys are used for applications in the automobile, aerospace and chemical industries because they have excellent corrosion resistances and high specific strengths. In addition, they can be used as biomaterials due to their good biocompatibilities. However, the major disadvantage with these materials is poor wear resistance. Since mechanical components and orthopedic implants with excellent tribological properties are required for practical use, techniques to harden the surface of titanium and its alloys have attracted great interest. Surface modification has been carried out by using various methods, such as gas nitriding,(1) plasma nitriding,(2,3) plasma carburizing,(4) and laser melting.(5) These methods need special equipment and complicated process flows to produce TiC and TiN layers on the base metal. Therefore, a simpler and quicker method is still desired.

The authors have previously investigated the interfacial microstructures and the bonding characteristics of titanium/steel and Ti–Al alloy/steel joints produced by explosive welding and diffusion bonding.(5–7) As part of these experiments, interfacial reactions between steel powder and titanium material were examined to consider the possibility of surface modification via pack cementation. As a result, we developed a simplified treatment for the diffusion of carbon and nitrogen into titanium. Specifically, a titanium plate is embedded in a mixture of steel and activated carbon powders and is heated at 1273 K for 3.6 ks in a nitrogen flow. During heating, a hardened layer, which has been identified as Ti(C, N), forms on the titanium surface. Matsuura et al. have proposed a method of forming a Ti(C, N) layer on a titanium surface.(8) In this method, a titanium specimen is heated in the temperature range of 1388–1573 K in a graphite cup under a nitrogen atmosphere. In contrast, our method uses steel powder and has the great advantage of using a lower heating temperature. Moreover, heat treatment using a mixture of steel and carbon (activated carbon and graphite) powders enables carburization of stainless steel which is covered with a passive film of chromium oxide.(9) Although such powder pack methods may not be industrially suitable, they are noteworthy because they allow carbon and nitrogen to be easily diffused into metal substrates.

In the present study, a new treatment for the diffusion of carbon and nitrogen using steel and carbon powders applied to titanium is described, and its effectiveness is discussed on the basis of the microstructures and the hardness in the vicinity of the titanium surface.

2. Experimental Procedure

A commercially pure titanium plate with a purity of 99.5 mass% was used as a substrate. The plate, which had a thickness of 1 mm, was cut into square shapes with dimensions of 10 mm × 10 mm, and the surface was finished with #1200 emery paper. The plates were then degreased in acetone using an ultrasonic cleaner and dried with hot air.

Mixtures of commercially available steel (carbonyl iron: 0.8–0.9 mass%C, 0.7–0.9 mass%N, 0.2–0.4 mass%O) and activated carbon powders were put into an alumina crucible, and the titanium plates were embedded in the mixtures. As shown in Fig. 1(a), the steel powder was fine and spherical. Figure 1(b) shows a scanning electron microscopic (SEM) image of the activated carbon powder. This was used as a carbon source and an anti-sintering agent. The volume ratio of the steel powder to the activated carbon powder was varied from 0 : 100 to 70 : 30. A further increase in the steel powder content made it difficult to take the specimen out of the powder mixture due to sintering. For comparison, graphite, which is shown in Fig. 1(c), was used instead of activated carbon. In some cases, alumina powder, shown in Fig. 1(d), was added to reliably prevent the powder mixture from sintering. The crucible packed with the titanium plate and the
powder mixture was placed in an electric furnace, as shown in Fig. 2. After repeatedly evacuating the furnace using a rotary vacuum pump and refilling it with nitrogen gas a few times, the crucible was heated in the temperature range of 773–1373 K for 3.6 ks in a nitrogen flow. The gas had a purity of >99.99 vol%, and its flow rate was 500 ml/min. All specimens were allowed to cool in the furnace to room temperature. In addition, a specimen heat-treated without the powder was prepared for comparison.

After heat treatment, X-ray diffraction (XRD) measurements, Vickers hardness tests and SEM observation were carried out on the titanium surfaces. In the hardness tests, a load of 0.49 N was applied at room temperature for 15 s. Thereafter, the specimens were cut in half to reveal the microstructures. The cross sections were ground with emery paper and then mirror-finished using diamond slurry with a particle size of 0.5 µm. They were examined by using optical microscopy, SEM in conjunction with energy dispersive X-ray spectroscopy (EDX), and electron probe X-ray microanalysis (EPMA). Before optical microscopy and SEM, the specimens were etched in an aqueous solution containing hydrofluoric acid and nitric acid (HF : HNO₃ : H₂O = 5 : 25 : 70 v/v/v).

3. Results and Discussion

3.1 Effects of a mixture of steel and activated carbon powders

Figure 3(a) shows an XRD pattern of a titanium plate alone after heat treatment at 1273 K for 3.6 ks in a nitrogen flow. The main reaction products were TiO₂ and Ti₂N. The formation of TiO₂ suggests the presence of a small amount of

![Fig. 1 SEM micrographs of (a) steel powder, (b) activated carbon powder, (c) graphite powder and (d) alumina powder.](image1)

![Fig. 3 XRD patterns of the surface of a titanium plate heat-treated at 1273 K for 3.6 ks in a nitrogen flow using various powders: (a) without powder, (b) activated carbon powder and (c) 10 : 90 (v/v) mixture of steel and activated carbon powders.](image3)
oxygen in the atmosphere, even though the furnace was purged with nitrogen. Next, a titanium plate was embedded in activated carbon powder and was treated under the same heating conditions. An XRD pattern of the surface, which was black in color, is shown in Fig. 3(b). Small diffraction peaks around 40° were identified as α-titanium and Ti2N, whereas the intense ones were roughly consistent with those for TiC and TiN. According to Matsuura et al., the large peaks indicate the formation of Ti(C, N). Figures 4(a) and 4(b) show optical and SEM micrographs of the cross section of the titanium plate heat-treated with the activated carbon powder, respectively. A reaction layer with a thickness of approximately 5 µm was observed on the titanium surface. On the basis of XRD patterns and compositional analysis, this layer was determined to be Ti(C, N). Thus, we concluded that the utilization of the activated carbon powder helped to prevent oxidation and to form the Ti(C, N) layer.

A titanium plate heat-treated at 1273 K for 3.6 ks in a nitrogen flow using mixtures of the steel and activated carbon powders became golden brown in color. Figure 3(c) shows an XRD pattern of the titanium surface after heat treatment using a 10:90 (v/v) mixture of steel and activated carbon powders. Addition of the steel powder caused the diffraction peaks for α-titanium and Ti2N to become smaller, whereas those for Ti(C, N) were more resolved. The XRD pattern was independent of the amount of steel powder in the powder mixture. The volume fractions of the steel powder used in Figs. 4(c) and 4(d) were 10 and 40 vol%, respectively. In comparison with Fig. 4(b), the Ti(C, N) layers formed on the titanium surface were remarkably thick. Therefore, the steel powder may contribute to enhancing the activities of carbon and nitrogen during heat treatment. In addition, a solid solution region, which was formed by the diffusion of carbon and nitrogen into titanium, was found along the Ti(C, N) layer. It should be noted that there were defects, such as voids, in the Ti(C, N) layers. Since the defects in the Ti(C, N) layers were observed in all cases, as shown in Fig. 4, the occurrence of defects is related to the formation of the Ti(C, N) layers. Furthermore, needle-shaped products formed in the titanium plates heat-treated in the powder. The microstructure corresponding to such products can be seen even in Fig. 4(a). They appeared after etching, and there were no obvious differences in the composition of the titanium matrix and the product. The defects in the Ti(C, N) layers and the needle-shape products are still under investigation.

The authors have reported that heat treatment in mixtures of steel and activated carbon powders results in the generation of carbon monoxide (CO) as the temperature is increased. This is probably due to chemical reactions between the carbon in the steel and activated carbon powders and residual oxygen in the furnace. CO generation was also confirmed in the present study. Since the free energy of formation for TiO2, which is predicted to exist on the titanium surface as an oxide film, is lower than that for CO, it is difficult to reduce the oxide film by CO directly. Since CO is exhausted with the nitrogen flow from the furnace, oxygen in the furnace should also be expelled. Accordingly, it is thought that a decrease in the oxygen partial pressure contributes to the decomposition of the oxide film on the titanium surface, making it easy for carbon and nitrogen to diffuse into the titanium.

Vickers hardness tests were carried out to reveal the effects of the powder mixture on the surface hardness of the heat-treated titanium plates. Figure 5 shows the relationship between the ratio of the steel powder in the powder mixture and the surface hardness of the titanium plates heat-treated at

---

**Fig. 4** (a) Optical and (b)–(d) SEM micrographs of cross section of a titanium plate heat-treated at 1273 K for 3.6 ks in a nitrogen flow using various powder mixtures. 1273 K for 3.6 ks in a nitrogen flow. The measurements were conducted at least seven times for each specimen. In each case, the surface hardness was more than HV = 1000 and was much higher than that of the untreated titanium plate, which had a hardness of HV = 190. The addition of the steel powder to the activated carbon powder resulted in a higher surface hardness. Although there was no significant change in Fig. 5, the titanium plate heat-treated in a 40 : 60 (v/v) mixture of the steel and activated carbon powders had a relatively high hardness. Therefore, it was used in subsequent experiments.

3.2 Effects of the heating temperature
To examine the relationship between the heating temperature and the formation of the Ti(C, N) layer, titanium plates were heat-treated at various temperatures in the 40 : 60 (v/v) steel/activated carbon mixture. XRD patterns of the titanium plates heat-treated at 873, 1073 and 1273 K are shown in Figs. 6(a)–6(c), respectively. The plates were held at each temperature for 3.6 ks in a nitrogen flow. At 873 K, no reaction products were detected, and all of the diffraction peaks corresponded to α-titanium. After heat treatment at 1073 K, the peaks for not only α-titanium but also β-titanium and Ti(C, N) were observed. The formation of β-titanium was attributed to the diffusion of iron, which is a β-stabilizer for titanium. The diffraction peaks for β-titanium and Ti(C, N) were too small, and they could not be identified in SEM images. As the heating temperature increased, the Ti(C, N) peaks became more intense. The titanium plate heat-treated at 1273 K was coated with a Ti(C, N) layer, as shown in Fig. 4(d), and this microstructural feature was reflected in the XRD pattern in Fig. 6(c).

Due to the Ti(C, N) layer, the surface hardness of the titanium plate heat-treated at 1373 K in the powder mixture was similar to that at 1273 K. Therefore, specimens with a Ti(C, N) layer had the highest hardness values, independent of the heating temperature. In other words, a heating temperature of >1273 K was necessary to form a uniform Ti(C, N) layer on the titanium surface. However, the heating temperature must be considered because the powder mixture, which is composed of steel and activated carbon powders, will melt at temperatures above the eutectic point (1426 K) in the Fe–C binary phase diagram.

3.3 Use of graphite and alumina powders
Instead of activated carbon, graphite was mixed with steel powder, and the effects of the carbon powder on the formation of the Ti(C, N) layer were examined. Figure 7 shows the surface hardness values of titanium plates heat-treated at 1273 K for 3.6 ks in a nitrogen flow using mixtures with different ratios of steel and graphite powders. In comparison with Fig. 5, it appears that there is little change in the average values and distributions of the surface hardness values. Since activated carbon has small pores and a high degree of microporosity, there is a risk of substances adsorbed in the pores, like water molecules, exerting some influence on the formation of the Ti(C, N) layer. Therefore, graphite is thought to be better suited as a carbon powder. Subsequently, alumina powder was added to the steel/graphite mixtures to make it easier to take the titanium plate out of the powder mixture after heat treatment. Figure 8 shows an SEM micrograph and compositional profiles of titanium, carbon and nitrogen near the titanium surface after heat treatment at 1273 K for 3.6 ks in a nitrogen flow using the powder mixture. The ratio of steel, graphite and alumina in the powder mixtures was 40 : 60 : 30 (v/v/v). After heat
treatment, the titanium plate was easily taken out of the powder mixture and had a Ti(C, N) layer on its surface. Considering the influence of etching conducted before observing the microstructures, the microstructure was similar to that in Fig. 4. This indicates that the use of graphite and alumina does not have a negative effect on the layer formation on the titanium surface. In the Ti(C, N) layer, the carbon content was similar to the nitrogen content, whereas the titanium content was slightly higher than the stoichiometric composition of TiC and TiN. According to the Ti–C and Ti–N binary phase diagrams,11,12) TiC and TiN have large composition ranges toward the titanium-rich side. This may be part of the reason for the formation of the titanium-rich Ti(C, N) layer. On the other hand, oxygen was scarcely detected in the compositional analysis.

The diffusion distances of carbon and nitrogen into α-titanium and β-titanium were evaluated by using $(2Dt)^{1/2}$, where $D$ and $t$ are the diffusion coefficient $(m^2/s)$ and the time $(s)$, respectively. When $t$ was 3600 s, the diffusion distance of nitrogen into α-titanium was estimated to be approximately 12 µm at 1273 K.13) This value is consistent with the compositional profile of nitrogen in Fig. 8. This also suggests that a phase transformation from β-titanium to α-titanium may take place in the subsurface region at 1273 K due to the diffusion of carbon and nitrogen, which are known to be α-stabilizers for titanium.

The surface morphological images of the specimen in Fig. 8 are shown in Fig. 9. It seems that the Ti(C, N) layer forms along the remaining traces of the mechanical grinding before heat treatment. Although minute irregularities and several voids were observed on the surface, the entire surface of the titanium plate was covered with a Ti(C, N) layer. The mechanical and chemical properties of titanium with a Ti(C, N) layer are currently being studied. However, the Ti(C, N) layer obtained in the present study is similar to that reported by Matsuura et al.8) in many respects. Therefore, it should have excellent wear and corrosion resistance.

4. Conclusions

Titanium plates were embedded in mixtures of steel and activated carbon powders and then heated in the temperature range of 773–1373 K for 3.6 ks in a nitrogen flow. The main results were as follows.

(1) Ti(C, N) layers with thicknesses of approximately 10 µm formed on the titanium surfaces when the plates were heat-treated at 1273 K for 3.6 ks using mixtures of steel and activated carbon powders. The surface hardness was more than HV = 1000 regardless of the steel powder ratio in the mixtures. The Ti(C, N) layers were thicker and harder when mixtures of steel and activated carbon powders were used, compared with when only the activated carbon powder was used.

(2) CO was detected in the gas exhausted from the furnace during heat treatment. As oxygen in the furnace reacts with carbon in the steel and activated carbon powders to form CO, the oxygen partial pressure should be low around the titanium plate. Therefore, it is thought that the decomposition of the oxide film on the titanium surface is promoted, making it easier for carbon and nitrogen to diffuse into the titanium.
From XRD results, Ti(C, N) began to form on the titanium plate heat-treated at 1073 K in a 40:60 (v/v) mixture of steel and activated carbon powders. At 1273 K, the titanium plate was coated with a Ti(C, N) layer and became golden brown in color.

Graphite was used instead of activated carbon, and alumina was added to the mixture of steel and graphite powders to reliably prevent the powder mixture from sintering. It was found that the addition of graphite and alumina powders did not have a negative impact on the formation of a Ti(C, N) layer on the titanium surface.
